Concurrency [27] refers to software systems whose functionality is expressed in terms of multiple components or processes that are specifically designed to work simultaneously with each other. In recent years, a concurrency-oriented [3] approach to software development has become increasingly commonplace, and is greatly favoured over monolithic-style approaches. This is, in part, owed to the rigidity that the latter types of architectures are synonymous with, where attempts at addressing scalability concerns usually lead to notoriously complex and often, inadequate solutions. Instead, concurrency recasts the notion of system design in a way that makes it possible to avail oneself of the multi-processor and multi-core platforms that are prevalent nowadays.

Formally ensuring the correctness of concurrent systems is an arduous, albeit necessary, task, especially since the interactions between fine-grained computational components can easily harbour subtle software bugs. Static verification techniques such as Model Checking (MC) scale poorly in these kinds of scenarios, particularly because the system state space that needs to be exhaustively verified grows exponentially w.r.t. the size of the system [13, 14], on account of the considerable number of possible execution paths that result from thread interleaving. Moreover, situations often arise whereby verification cannot be performed statically (i.e., pre-deployment), as certain application components might not always be available for inspection before the system starts executing (e.g. in systems where functional components such as add-ons are downloaded and installed dynamically at runtime). There are also cases whereby the component internal workings (e.g. source code or execution graph) are not accessible and need to be treated as a black box. In these cases, Runtime Verification (RV) presents an appealing compromise towards ensuring the correctness of component-based applications. It is a *lightweight* verification technique that analyses the current runtime execution path of the system under scrutiny by considering partial executions incrementally, up to the current execution point [16, 24]. Its nature inherently circumvents the scalability issues attributed to MC and provides a means for post-deployment verification. Despite these advantages, RV has limited expressivity and cannot be used to verify arbitrary specifications such as (general) liveness properties [25].

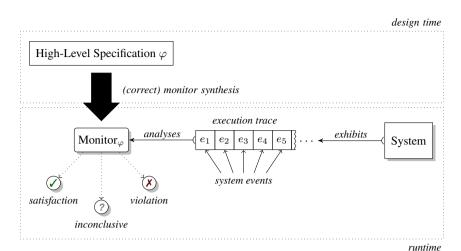

Figure 1.1 Runtime monitor synthesis and operational setup.

This chapter discusses the implementation of a prototype RV tool called detectEr, that targets concurrent, component-based applications written in Erlang. The presented material aspires to introduce this tool from a pragmatic standpoint, and thus, omits technical details that may be abstruse to users of the tool. Interested readers should consult [18, 4, 20], for specifics regarding the monitor synthesis and runtime behaviour of the monitoring tool.

The presentation is organised into three sections. Section 1.1 briefly overviews the main ideas behind RV and monitoring; this is followed by a review of mHML, the logic used for specifying correctness properties in our tool. Although this section helps to make the presentation self contained, it may be safely skipped by readers familiar with this material or merely interested in using the tool. Section 1.2 revisits the logic mHML from Section 1.1, and examines how this was adapted to address the pragmatic needs of a user defining correctness properties for Erlang concurrent programs. It also very briefly touches on the compilation process that transforms mHML specification scripts into executable runtime monitors. The final section takes the form of a quick tutorial that guides readers through the basic steps that need to be performed in order to instrument an Erlang application with runtime monitors via the tool.

1.1 Background

An executing system results in the generation of a (possibly infinite) sequence of events known as a *trace*. These events are the upshot of internal or external system behaviours, such as message exchanges between processes or function invocations. An *execution*, *i.e.*, a *finite prefix* of an infinite trace, is consumed and processed by a software entity known as a *monitor*, tasked with the job of checking whether the execution provides enough evidence so as to determine whether a property is satisfied or violated. *Correctness specifications* (*properties*) serve to unambiguously describe the behaviour to which the executing system should adhere to. *Verdicts* denote monitoring outcomes; these are assumed to be definite and cannot be retracted. They typically consist of judgements relating to property violations and satisfactions, but may also include *inconclusive* verdicts for when the exhibited execution trace does not permit any definite judgement in relation to the property being monitored for [16, 24, 6, 18, 4]. A RV monitor for some correctness property is typically synthesised automatically from a high-level specification that finitely describe these properties, given in terms of formal logics [4, 6, 7, 18] or other formalisms such as regular expressions [19] or

Syntax

```
\varphi, \phi \in \mu HML ::= ff \text{ (falsity)}
                                                                               tt (truth)
                        \varphi \wedge \phi (conjunction)
                                                                               \varphi \lor \phi (disjunction)
                            [\alpha]\varphi (necessity)
                                                                               \langle \alpha \rangle \varphi (possibility)
                            \max X.\varphi (max. fixpoint)
                                                                               \min X.\varphi (min. fixpoint)
                           X (recursive variable)
```

Semantics

```
\stackrel{\text{def}}{=} PROC
\llbracket \mathsf{ff}, \rho \rrbracket
                                                                                                                                                                                                          \llbracket \mathsf{tt}, \rho \rrbracket
                                                                                                                                                                                                          \llbracket \varphi \vee \phi, \rho \rrbracket \quad \stackrel{\mathrm{def}}{=} \llbracket \varphi, \rho \rrbracket \cup \llbracket \phi, \rho \rrbracket

Figure 1.2 The syntax and semantics of μ HML.

automata [5, 15, 26]. Figure 1.1 depicts a correctness specification (denoted by φ) that is translated into an executable monitor, Monitor $_{\varphi}$, and instrumented with the running system. Trace event messages are sequentially analysed by the monitor whenever these are generated by the system via the instrumentation. Once the monitor reaches verdict, it typically stops executing.

1.1.1 Runtime Monitoring Criteria

Monitor synthesis, i.e., the translation procedure from specifications to monitors and the associated system instrumentation, should provide some *guarantees* of correctness. This covers both aspects relating to how monitor verdicts correspond to the semantics of the property being monitored for (e.g. a monitor trace rejection should correspond to the system violating the resp. property being monitored for), as well as requirements that the monitors instrumented with the executing system under scrutiny do not introduce fresh bugs themselves. (see [18, 20, 9, 17] for a detailed rendition on the subject). Equally important is the efficiency with which monitors execute, as this can adversely affect the monitored system or even alter its functional behaviour (e.g. slowdown due to inefficient monitors might cause the system to violate time-dependent properties that would not have been violated in the unmonitored system). Moreover, a monitoring setup that induces considerable levels of performance overheads may be deemed too costly to be feasibly used in practice.

1.1.2 A Branching-Time Logic for Specifying Correctness Properties

Specification logics can be categorised into two classes. *Linear-time* logics [24, 6, 13], treat time as having one possible future, and regard the behaviour of a system under observation in terms of execution traces or paths. Contrastingly, branching-time logics [1, 13] make it possible to perceive time instances as potentially having more than one future, thereby giving rise to a tree of possible execution paths that may be (non-deterministically) taken by the executing system at runtime.

 μ HML [23, 1] is a branching-time logic that can be used to specify correctness properties over Labelled Transition Systems (LTSs) — graphs modelling the possible behaviours that can be exhibited by executing processes (see Figure 1.3 for a depiction of two LTSs).

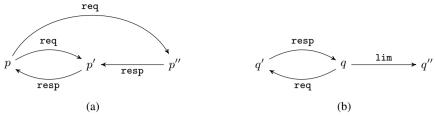

Figure 1.3 The LTSs depicting the behaviour of two servers p and q.

A LTS consists of a set of system states $p, q \in SYS$, a set of actions $\alpha \in ACT$, and finally, a ternary transition relation between states labelled by actions, $p \xrightarrow{\alpha} q$. The μ HML syntax, given in Figure 1.2, assumes a countable set of logical variables $X, Y \in LVAR$, thereby allowing formulae to recursively express maximal and minimal fixpoints using $\max X.\varphi$ and $\min X.\varphi$ respectively; these bind free instances of the variable X in φ . In addition to the standard constructs for truth, falsity, conjunction and disjunction, the syntax also includes the necessity and possibility modalities. The semantics of the logic is defined in terms of the function mapping between μHML formulae φ and the set of LTS states $S \subseteq 2^{SYS}$ satisfying them. Figure 1.2 describes the semantics for both open and closed formulae, and uses a map $\rho \in \text{LVAR} \rightarrow 2^{\text{SYS}}$ from variables to sets of system states to enable an inductive definition on the structure of the formula φ . The truth value **tt** is satisfied by all processes, while ff satisfied by none; conjunctions and disjunctions bear the standard set-theoretic meaning of intersection and union. Necessity formulae $[\alpha]\varphi$ state that for all system executions producing event α (possibly none), the subsequent system state must then satisfy φ , whereas possibility formulae $\langle \alpha \rangle \varphi$ require the existence of *at least* one system execution with event α whereby the subsequent state then satisfies φ . The recursive formulae $\max X.\varphi$ and $\min X.\varphi$ are resp. satisfied by the largest and least set of system states satisfying φ . The semantics of recursive variables X w.r.t. an environment instance ρ is given by the mapping of X in ρ , i.e., the set of processes associated with X. Closed formulae are interpreted independently of the environment ρ , and the shorthand $\llbracket \varphi \rrbracket$ is used to denote $[\![\varphi,\rho]\!]$, i.e., the set of system states in SYS that satisfy φ . In view of this, we say that a system (state) p satisfies some formula φ whenever $p \in [\![\varphi]\!]$, and conversely, that it violates φ whenever $p \notin \llbracket \varphi \rrbracket$.

Example 1.1.1. The μ HML formula $\langle \alpha \rangle$ tt describes systems that *can* produce action α , while $[\alpha]$ ff describes systems that *cannot* produce action α .

$$\begin{split} \varphi_1 &= \max X. \big([\texttt{req}] ([\texttt{resp}] X \wedge [\texttt{resp}] [\texttt{resp}] \texttt{ff}) \big) \\ \varphi_2 &= \min X. (\langle \texttt{req} \rangle \langle \texttt{resp} \rangle X \vee \langle \texttt{lim} \rangle \texttt{tt}) \end{split}$$

The formula φ_1 describes a property that prohibits a system from producing duplicate responses when answering to client requests; system p whose LTS is depicted in Figure 1.3 violates φ_1 via the trace $(\text{req.resp})^+$.resp. The formula φ_2 describes systems that can reach a service limit after a number (possibly zero) of request and response interactions; system q depicted in Figure 1.3 satisfies φ_2 through the trace $(\text{req.resp})^*$.lim.

1.1.3 Monitoring μ HML

Despite its limitations (*i.e.*, monitors can only analyse single execution traces), RV can be still effectively applied in cases where correctness properties can be shown to be satisfied (or violated) by analysing a single finite execution — such executions may of course be partial,

Monitorable Logic Syntax

 $\psi \in \mathrm{mHML} \stackrel{\mathrm{def}}{=} \mathrm{sHML} \cup \mathrm{cHML}$ where: $\mid X$ $\theta, \vartheta \in \mathrm{sHML} ::= \mathsf{tt}$ ff $\mid \theta \wedge \vartheta$ | max $X.\theta$ $[\alpha]\theta$ $\pi, \varpi \in \mathrm{cHML} ::= \mathsf{tt}$ $\min X.\pi$ ff $\pi\vee\varpi$ $\langle \alpha \rangle \pi$ $\mid X$ Figure 1.4 The syntax of mHML.

up to the current execution point of the system [20]. For instance, the formula $[\alpha]$ ff state that all α -actions performed by a satisfying system should satisfy property **ff** afterwards. Since no system state can satisfy ff, the only way how to satisfy $[\alpha]$ ff is for a system not to perform α . From an RV perspective, for a monitor to detect a violation of this requirement, observing one negative witness execution trace that starts with action α suffices to show that property φ is infringed.

Example 1.1.2. μ HML formula $\varphi_3 = \langle \text{lim} \rangle$ tt requires that "a process can perform action lim". System q in Figure 1.3b, can exhibit the trace of the form $\lim \epsilon$ which suffices to show that system q satisfies φ_3 . The system may also exhibit other traces, such as those of the form (req.resp)* which all start with the event req. Such traces do not provide enough evidence that system q satisfies φ_3 . Stated otherwise, the monitor for formula φ_3 can only arrive to an acceptance verdict only when a trace starting with event lim action is observed. Otherwise, no verdict relating to the satisfaction or violation of the formula can be reached; in our specific case, the monitors we consider will reach the inconclusive verdict.

The availability of a single finite runtime trace does however restrict the applicability of RV in cases such as those involving correctness properties describing *infinite* or *branching* executions. In view of this, certain properties expressed using the full expressive power of a branching-time logic such as μ HML cannot be monitored for at runtime. The work in [18] explores the monitorable limits of μ HML, identifies a syntactic logical subset called mHML, and shows it to be monitorable and maximally-expressive w.r.t. the constraints of runtime monitoring. Its syntax, given in Figure 1.4, consists of two syntactic classes, Safety HML (sHML), describing invariant properties stipulating that bad things do not happen, and Co-Safety HML (cHML), describing properties that eventually hold after a finite number of events [2, 6, 22]. Formulae φ_1 and φ_2 from Example 1.1.1 are instances of sHML and cHML specifications respectively.

1.2 A Tool for Monitoring Erlang Applications

We briefly review the implementation of our RV tool detectEr that analyses the correctness of concurrent programs developed in Erlang. It builds on the results in [18], where a synthesis procedure is defined generating *correct* monitor descriptions from formulae written in mHML. We adapt the synthesis procedure of [18] so as to generate concurrent monitors as Erlang actors, that are instrumented with the running system via the tracing mechanism offered by the VM of the host language. The synthesis procedure exploits the compositional semantics of the respective mHML formulae to generate a choreography of monitor (actor) components that independently analyse individual sub-fomulas of a global property, while still guaranteeing the correctness of the overall monitoring process.

In the sequel we will not go into the specifics of how the concurrent monitors are synthesised; the reader is encouraged to consult [4, 20], where the synthesis is discussed at length. Instead, we limit ourselves to a high-level description the main concepts and technologies

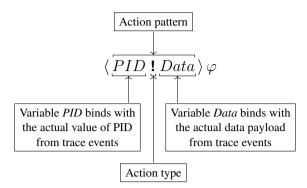

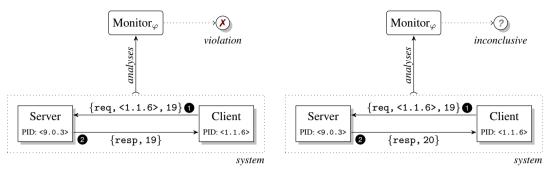

Figure 1.5 The anatomy of action patterns for the enriched mHML syntax.

required by the reader to be able to adequately use the monitor tool. In particular, we discuss the mechanisms of the host language used by the tool, the adaptations to the specification logic that facilitate the handling of data, and finally overview the compilation process of the tool.

1.2.1 Concurrency-Oriented Development Using Erlang

Erlang is a general-purpose, concurrent programming language suitable for the development of fault-tolerant and distributed systems [3, 12, 21]. It adopts the actor model for concurrency as the primary means for structuring its applications. An *actor* is a concurrency unit of decomposition that represents a processing entity sharing no mutable memory with other actors. It interacts with other actors by sending (asynchronous) messages, and changes its internal state based on the messages received from other actors. In Erlang, actors are implemented as lightweight processes that are uniquely identified via their process PID (a number triple). Each process owns a message queue, known as a *mailbox*, to which messages from other processes can be sent in a non-blocking fashion; these can be consumed selectively at a later stage by the recipient process. Messages are comprised of Erlang data types, including integers, floats, atoms, functions, binaries, *etc.*. Since process PIDs are allocated dynamically when spawned, Erlang provides a mechanism for registering a PID with a fixed alias name. This allows external entities to refer to a specific process statically, via the registered name alias [3, 12].

The Erlang Virtual Machine (EVM) offers a powerful and flexible *tracing* mechanism, making it possible to observe process behaviour *without needing to modify* the system source code through commonly used instrumentation techniques such as Aspect Oriented Programming (AOP) [3, 12]. Its flexibility stems from the fact that it can be *selectively* applied on specific processes as required, thereby fine tuning the tracing effort to the desired level of granularity. When traced, processes generate *action* messages that are directed by the Erlang runtime to a specially designated *tracer* process. Trace messages assume the form of Erlang *tuples* that describe the nature of trace events (*e.g.* function calls, message sends and receives, garbage collection triggers, *etc.*) and are deposited (like any other message) asynchronously inside the tracer's mailbox. Tracing serves as the basis for a number of utilities, including Erlang's text-based tracing facility dbg, and trace tool builder ttb [3]. Our tool, detectEr, employs this tracing mechanism to achieve *lightweight* trace event extraction for monitoring purposes; consult [4] for details.

- (a) The incorrect server implementation.
- (b) The correct server implementation.

Figure 1.6 Runtime verifying the correctness of a client-server system.

1.2.2 Reasoning about Data

Adapting mHML to be used for specifying the behaviour of Erlang programs adequately requires auxiliary functionality that describes system events carrying data: this involves mechanisms for generalising over specific data values and for expressing data dependencies. Our tool assumes a richer set of system events that carry data. Our exposition focusses on two types of events, namely outputs i!d and inputs i?d, where i ranges over process PIDs, and d denotes the data payload associated with the action in the form of Erlang data values (e.g. PID, lists, tuples, atoms, etc.); in practice, the tool handles other events such as function calls and returns. In addition, our tool enriches the syntax of Figure 1.4 by introducing pattern-matching extensions for event actions (see Figure 1.5). Necessity and possibility formulae may contain event patterns instead of specific events: these possess the same structure of the aforementioned data-carrying events, but may also employ variables (Erlang-style alphanumeric identifiers starting with an upper-case letter) in place of values. Variables denote quantifications over data and are dynamically bound to values when they are pattern-matched to specific system events at runtime. Event patterns also allow us to express data dependencies across multiple events: intuitively, whenever a variable is used in a pattern of a necessity or possibility formula and again in the ensuing guarded subformula, the foremost variable instance acts as a binder for subsequent variable uses.

Example 1.2.1. The client-server setup shown in Figure 1.6 consists of a successor server process (with PID <9.0.3>) that increments the numeric payloads it receives from requesting clients by 1. Client requests should adhere to the following protocol. A client sends a tuple of the form $\{tag, return_addr, value_to_increment\}$ where the first element is a qualifier tag stating that it is a client request (tag = req). The client then awaits for an answer back from the server in the form of a message with format $\{resp, incremented_value\}$. The server obtains the identity of the client to whom to send the incremented value back to from the client request data $return_addr$, which should carry the PID of the client sending the request (e.g. < 1.1.6 > in the case of Figure 1.6b). One attempt at verifying the correctness of the executing system is by specifying a safety property stating that

"the numeric payload contained in the server's response cannot equal the one sent in the original client request."

This requirement can be expressed as follows:

$$\varphi_4 = [Srv ? \{req, Clt, Num\}] [Clt ! \{resp, Num\}] ff$$

The two necessity constructs in the sHML formula φ_4 describe a request-response interaction between the client and server processes. The first necessity $[Srv\ ?\ \{req, Clt, Num\}]$ specifies an *input* event data pattern that conforms to the structure of the data sent by the client when initiating its interaction with the server (i.e., the action labelled by \bullet in Figure 1.6); meanwhile, the second necessity $[Clt\ !\ \{resp, Num\}]$ if specifies an *output* action data pattern that conforms to the structure of the data sent by the server in reply to the client's request (i.e., action \bullet in Figure 1.6). Formula φ_4 matches events in the execution trace whenever the server Srv receives a request with numeric payload Num from client Clt, and replies back to the same client Clt with the same value Num. Note the dependency between the patterns in the two necessities: the values matched to the variable Clt and Num in first pattern are then instantiated in the subsequent necessity pattern.

To illustrate concretely how binding actually works, we can consider how the two different executions of client-server system depicted in Figures 1.6a and 1.6b are monitored at runtime. When the event pattern Srv ? {req, Clt, Num} from the first necessity is matched to the first trace event <9.0.3>? {req, <1.1.6>, 19} (resulting from the execution of action **1**), the pattern variables Srv, Clt and Num become bound to the runtime values <9.0.3>, <1.1.6> and 19 respectively. This leaves us with the residual formula [<1.1.6>! {resp, 19}] ff to check for, where the runtime binding of variables Srv, Clt and *Num* instantiates the subsequent (guarded) patterns to specific values learnt at runtime. This closed formula can now match the second trace event (due to action 2), only if an incorrectly implemented server responds to the preceeding client with the same numeric payload sent to it, as is the case in Figure 1.6a, which in turn leads to a violation detection. Contrastingly, Figure 1.6b shows the case where server's reply sent back to the client contains the value 20 which does not match the runtime binding for the subformula [Clt ! {resp, Num}] ff of φ_4 : after the first pattern-match Num is bound to 19, which mismatches with event {resp, 20} of action 2 in Figure 1.6b (Clt is bound to <1.1.6> as before). This leads to an inconclusive verdict.

1.2.2.1 Properties with specific PIDs

Since process PIDs are allocated at runtime, there is no direct way for a correctness property to refer to a *specific* process. Nevertheless, the tool still provides an indirect method how to specify this via the process PID registering mechanism offered by the host language. For instance, in the case of formula φ_4 from Example 1.2.1, one could refer to a particular process (instead of *any* arbitrary process that is dynamically bound to variable Srv in the pattern $[Srv\ ?\ \{req, Clt, Num\}]$) using the notation @srv in place of Srv. This would then refer to the process that is registered with the fixed (atom) name srv in the system and the respective event analysis would only match with events sent specifically to the process whose PID is registered to srv.

1.2.2.2 Further Reasoning about Data

Readers might have been wary of the fact that formula φ_4 in Example 1.2.1 only guards against cases where the server merely *echoes* back the same numeric payload sent to it by clients. This only partially addresses the ideal correctness requirements, because it does not capture the full behaviour expected of the successor server in Figure 1.6. For instance, reformulating the property from Example 1.2.1 to read as

"the numeric payload contained in the server's response must be equal to the successor of the one sent in the original client request."

requires the monitor to check whether all responses issued by the server in reply to client requests do in fact contain the successor of the number enclosed in said requests.

Our logic handles this expressivity requirement by extending the enriched mHML syntax from Section 1.2.2 with conditional constructs and predicates, thus enabling it to perform complex reasoning on the data values obtained dynamically through pattern matching. Data predicates are assumed to be decidable¹, and together with boolean expressions, are evaluated to values $b \in \{\text{false, true}\}$. Conditionals, written as if b then θ else θ for sHML formulae and if b then π else ϖ for cHML formulae, evaluate to θ and π respectively when b evaluates to true, and to ϑ and ϖ otherwise. The **else** clause may be omitted if not required. Correctness formulae of the latter form are given an *inconclusive* interpretation whenever the boolean condition inside the if clause evaluates to false. Conditional constructs increase the expressivity of mHML, because they make it possible to formalise properties that are otherwise hard to express using the basic form of the logic. When compiled, conditional formulae are translated into monitors whose runtime analysis branches depending on dynamic decisions made on data acquired at runtime.

Example 1.2.2. The reformulated safety property "the numeric payload contained in the server's response must be equal to the successor of the one sent in the original client request" can be specified as follows using the extended sHML syntax:

$$arphi_5 = [\mathit{Srv}~ extbf{?}~ \{\mathtt{req}, \mathit{Clt}, \mathit{Num}\}] \, [\mathit{Clt}~ !~ \{\mathtt{resp}, \mathit{Succ}\}] \, \, \mathsf{if}(\mathit{Succ} \neq \mathit{Num} + 1) \, \mathsf{then} \, \mathsf{ff}$$

Formula φ_5 differs slightly from the one specified in Example 1.2.1: it introduces a new variable Succ that binds to the server's return value. This, in turn, enables the conditional construct to determine whether the successor operation is correctly implemented by the server, thus ensuring that φ_5 is violated only when the value bound to *Succ* is not the successions. sor of Num. An inconclusive verdict is assumed by the formula whenever $(Succ \neq Num+1)$ does not hold, i.e., Succ is indeed the successor of Num, as in the case of Figure 1.6b.

1.2.3 Monitor Compilation

Following closely the synthesis function of [4], our tool is able to parse mHML formulae and generate Erlang code that monitors for resp. formulae. The inherent concurrency features offered by Erlang, together with the modular structure of the synthesis function are used to translate formulae into choreographed collections of (sub)-monitors expressed as concurrent processes that execute independently of one another and analyse different parts of the exhibited system trace: e.g. one submonitor may be analysing the second event in an execution trace of length five, whereas another may forge ahead and analyse the fourth event in the trace. In order to ensure that submonitors have access to the same trace events, they are organised as supervision trees [3, 12]: the (parent) monitor to which the submonitors are attached forks (i.e., replicates and forwards) individual trace events to its children; the moment a verdict is reached by any submonitor process, all monitoring processes are terminated, and said verdict is used to declare the final monitoring outcome. The interested readers should consult [4, 20], for details on how the monitor choreographies are organised.

Figure 1.7 outlines the compilation steps required to transform a formula script file, e.g. script.hml, into a corresponding Erlang source code implementing the monitor, i.e., monitor.erl. The tool instruments the synthesised monitors to run asynchronously with the system to be analysed using the native tracing functionality provided by the EVM. Crucially, this type of instrumentation requires no changes to the monitor source code (or the target system binaries): in Figure 1.7, the file packaging component of the compiler leaves the system source files unchanged. This increases confidence in the correctness of the

¹ They are a restricted subset of the Erlang boolean expressions used as guards; they are side-effect free and are guaranteed to terminate [12].

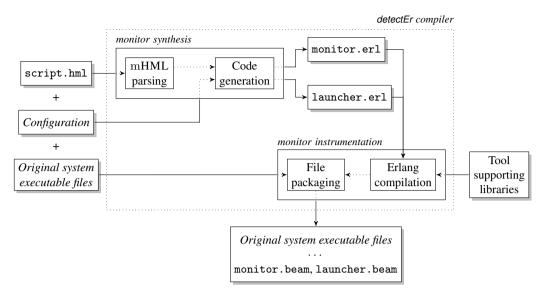

Figure 1.7 The monitor synthesis process and instrumentation pipeline.

generated monitoring setup. In addition to the monitor source file, Figure 1.7 shows a second module called launcher.erl which is generated automatically based on the specified system start up configuration — this is tasked with responsibility of launching the system and corresponding monitors in tandem. Said modules, together with other supporting tool-related source code files are then compiled into executable modules (.beam files), which are then packaged and placed alongside other system binary files.

1.3 detectEr in Practice

We revisit the runtime monitoring tool depicted in Figure 1.7 from a user's perspective, and present a brief guide showcasing its main functionality. This guide is in the form of a tutorial that goes through the steps required to apply our tool to monitor an Erlang implementation of the client-server system seen earlier in Example 1.2.1. It shows how a simple (but useful) safety property can be scripted as a sHML formula, and compiled into a runtime monitor that is used to verify the incorrect and correct behaviour of the successor server, as illustrated in Figures 1.6a and 1.6b. cHML properties from Figure 1.4 may also be monitored for using the same sequence of steps.

Presently, the current prototype tool implementation is capable of instrumenting only one monitor inside the target system. Nevertheless, the tool's compilation and instrumentation processes were developed with extensibility in mind, and the steps that are outlined in the following tutorial remain valid once the tool is extended to support multiple monitors. Although the example presented in this guide is fairly basic, it conveys the essence of how the tool should be applied in practice; more complex properties, such as those found in [8, 10], would be built following the same instructions and procedures outlined in the coming sections.

1.3.1 Creating the Target System

The initial distribution of the tool is available from https://bitbucket.org/duncanatt/detecter-lite, and requires a working installation of Erlang. This guide assumes that GNU make is installed on the host system. OSX users can acquire make by installing

the XCode Command Line Tools: Windows users can install the MinGW suite of tools. Although Linux was used to create this tutorial, the steps below can be replicated on any other operating system.

1.3.1.1 Setting Up the Erlang Project

To facilitate the development of Erlang applications, detectEr includes a generic makefile which we use in this guide. The following make targets are provided:

- init: Creates the standard Erlang project structure;
- clean: Removes Erlang . beam and other temporary files;
- all: Cleans and compiles the Erlang project;
- instrument: Synthesises and instruments monitors into the target system, given the HML script, target system binary directory and application entry point configuration.

We begin by creating a target directory called example. This contains the client-server system Erlang project and all its associated source code files. At the root of the example directory, we also place the aforementioned makefile, since this is used to manage the build process of our simple Erlang application. The latest version of the makefile can be downloaded directly from the project site using wget:

```
duncan@term:/$ mkdir example
duncan@term:/$ cd example
duncan@term:/example$ wget https://bitbucket.org/duncanatt/detecter-lite\
/raw/detecter-lite-1.0/Makefile
```

Once the makefile is downloaded, the standard Erlang directory structure is created using the init target:

```
duncan@term:/example$ make init
duncan@term:/example$ ls -1
drwxrwxr-x 2 duncan duncan 4096 May 15 16:53 include
-rw-rw-r-- 1 duncan duncan 5463 May 15 16:53 Makefile
drwxrwxr-x 2 duncan duncan 4096 May 15 16:53 src
drwxrwxr-x 2 duncan duncan 4096 May 15 16:53 test
```

To avoid writing the Erlang server manually from scratch, the guide borrows a number of sample source code files that are included in the tool's distribution. For simplicity, we assume that the tool is set up in the same directory as our example project directory. The plus_one module that forms part of the tool distribution, implements a version of the successor server as described in Figure 1.6. This file, together with its dependencies should be copied into the src and include directories as shown below; these commands should result in a directory structure that corresponds to the one shown in Figure 1.8a.

```
duncan@term:/example$ cd src
duncan@term:/example/src$ cp ../../detecter-lite/test/plus_one.erl .
duncan@term:/example/src$ cp ../../detecter-lite/src/mon/log.erl .
duncan@term:/example/src$ cd ../include/
duncan@term:/example/include$ cp ../../detecter-lite/include/* .
```

After the files have been copied successfully into their respective directories, the Erlang project can be built by invoking make:

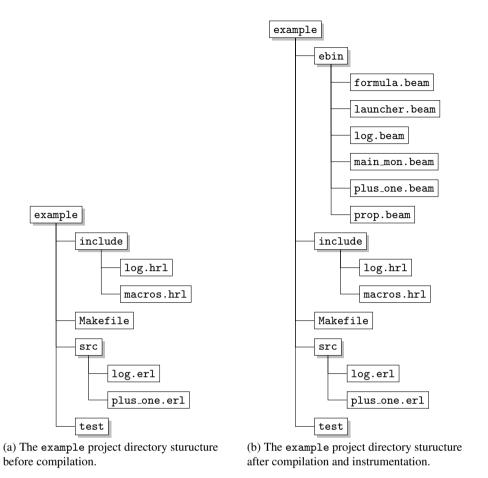

Figure 1.8 Creating the Erlang project directory structure.

```
duncan@term:/example/include$ cd ..
duncan@term:/example$ make

Compiling Erlang source file: src/log.erl to ebin/log.beam

Compiling Erlang source file: src/plus_one.erl to ebin/plus_one.beam

>-------

Build completed successfully!

>--------
```

1.3.1.2 Running and Testing the Server

With the build now completed, the plus_one successor server can be launched and tested. Since we have not developed a complete application, but only the server part, testing is conducted using the Erlang shell in place of a full client implementation. For illustrative purposes, the plus_one server may exhibit different behaviours at runtime depending on the flag it is started up with. Concretely, the plus_one server and shell can be launched from the terminal as follows:

```
duncan@term:/example$ erl -pa ebin -eval "plus_one:start(bad)"

Erlang/OTP 18 [erts-7.2] [source] [smp:4:4] [async-threads:10] [kernel-poll:false]
```

```
[<0.2.0> - plus_one:22] - Started PLUS ONE server with initial value '0' and mode 'bad'.
5
  Eshell V7.2 (abort with ^G)
6
  1> _
```

The plus_one server is intentionally started using the startup flag bad, in order to simulate the incorrect server behaviour depicted in Figure 1.6a. This serves its purpose later when scripting the formula used to verify the server's behaviour. We can confirm that the server started up successfully by ensuring that the plus_one start up log (line 4) shows up in the terminal. Once loaded, the server can be tested by submitting requests to it using the Erlang! (send) operator (line 7 below). Following the protocol outlined in Example 1.2.1, the test request is sent to the process identified by the Erlang registered process name plus_one, follows the tuple format {request, return_addr, value_to_increment}, where return_addr corresponds to the PID of the sender actor (in this case, the Erlang shell), and value_to_increment contains the actual numeric data payload, i.e., the number the client wishes to increment. In Erlang, a process may obtain its own PID through the function call self(). Note that commands typed in the Erlang shell must terminate with a period symbol, otherwise these will not be processed.

```
1> plus_one ! {req, self(), 19}.
8
9
    [ <0.33.0> - plus_one:41] - Received request with value '19'.
10
    [<0.33.0> - plus_one:46] - Sending response with value '{resp,19}', Current cnt '1'.
11
   {req,<0.36.0>,19}
   2>_
12.
```

As can be gleaned from the logs above, the plus_one server receives the number '19' as payload, and echoes back that same value to the shell (lines 9-10). A correct implementation of the server should have replied with a value of '20', that corresponds to the client's request being incremented by '1'. The server's response can be extracted from the Erlang shell by invoking the flush() function to empty the shell's mailbox (line 13). After confirming that the server is working (incorrectly) as intended, the Erlang shell can be closed by typing "q()." at the terminal.

```
13 2> flush().
14
   Shell got {resp, 19}
15
16 3> _
```

1.3.2 Instrumenting the Test System

We are now in a position to generate a monitor that verifies the safety property below, a generalisation of the property discussed earlier in Example 1.2.1:

"After any sequence of request-response interactions with arbitrary clients, the numeric payload contained in the server's response following a client request must never equal the one sent in the original client request."

The monitor synthesised for this property should detect the violating behaviour exhibited by the plus_one server.

1.3.2.1 Property Specification

Properties using our tool are specified in plain text files. These are processed to produce monitors in the form of Erlang code. These, together with other supporting source files, are compiled to executable Erlang .beam files and copied into the target system's binary directory, ebin. As explained in Section 1.2.3, the tool also creates a launcher module that is used to bootstrap the system together with the synthesised monitor. Once loaded, the system executes as it normally would, while concurrently, the monitor passively observes the system's behaviour expressed in terms of the messages exchanged between it and its environment. A violation will be promptly flagged when discovered by the monitor analysing the trace generated by our successor server. The aforestated safety property can be scripted by pasting the sHML formula given below into a plain text editor, and saving it as prop.hml *in* the example directory.

```
1 max('X',
2  [Srv ? {request, Clt, Num}][Clt ! {result, Num}] ff
3  &&
4  [Srv ? {request, Clt, Num}][Clt ! {result, Other}] 'X')
```

This recursive sHML formula makes use of a conjunction (&&) construct to express the two possible behaviours expected of the system. The violating behaviour, specified using [Srv ? {request, Clt, Num}] [Clt! {result, Num}] ff, demands that a violation be flagged when the server Srv receives a request containing Num from client Clt, and returns to Clt the same value Num. The recursive (non-violating) behaviour, expressed by [Srv ? {request, Clt, Num}] [Clt ! {result, Other}] 'X', requires the monitor to recurse whenever whenever a request received from Clt is answered with some value Other, i.e., not just the successor of Num. This is in line with the property above, as it requires the monitor to detect violations only when the same value of Num is returned by a server in reply to a client's request. Recursion, made possible by the maximal fixpoint construct max('X', ...) and the recursive variable 'X', allows the monitor to unfold repeatedly, thereby continuously analysing the system trace until the violating behaviour is detected. Note that the formula in prop. hml is an extension to the simpler property φ_4 from Example 1.2.1. In φ_4 , the absence of recursion permits the corresponding monitor to analyse, at most, two trace events before terminating. Note also that a more comprehensive interpretation of the aforementioned correctness property would of course require the formula to check that each number in the server's response actually succeeds the one sent in the client's request, as discussed earlier in Example 1.2.2. This can be expressed by modifying line 4 in the above script to

```
max('X', ... &&
  [Srv ? {request, Clt, Num}][Clt ! {result, Other}] if Other == Num + 1 then 'X')
```

In what follows, we stick to the weaker variant of the property to simplify our presentation.

1.3.2.2 Monitor Synthesis and Instrumentation

The monitor corresponding to the sHML script created above is synthesised using the instrument target from the application makefile:

```
duncan@term:/example$ cd ../detecter-lite
duncan@term:/detecter-lite$ make instrument hml="../example/prop.hml"\
app-bin-dir="../example/ebin"\
MFA="{plus_one,start,[bad]}"
```

The instrument target requires the following command line arguments:

• hml: The relative or absolute path that leads to the formula script file;

- app-bin-dir: The target application's binary base directory;
- MFA: The target application's entry point function, encoded as a {Mod, Fun, [Args]} tuple, where we specified the plus_one module's start function passing eql as the argument, as done previously.

Monitor synthesis and instrumentation (refer to Figure 1.7) results in the Erlang project directory structure shown in Figure 1.8b. All the original target system binaries remain untouched, and the plus_one server application can be still run without monitors, as before (see Section 1.3.1.2).

1.3.2.3 Running the Monitored System

The instrumented system can be started up by using the automatically generated launcher module as shown:

```
duncan@term:/example$ erl -pa ebin -eval "launcher:start()"
2
3
   Erlang/OTP 18 [erts-7.2] [smp:4:4] [async-threads:10] [kernel-poll:false]
 4
    [<0.34.0> - main_mon:38] - Started main monitor for processes/PIDs [].
 5
    [<0.33.0> - plus_one:22] - Started PLUS ONE server with initial cnt value '0' and mode 'bad'.
    [<0.33.0> - main_mon:24] - System to be monitored started.
8
   Eshell V7.2 (abort with ^G)
    [<0.34.0> - main_mon:62] - Resolved procs [].
    [<0.40.0> - formula:152] - mon_max adding var 'X' to formula env.
10
    [\langle 0.40.0 \rangle - \text{formula:91}] - \text{mon\_and spawned processes } \langle \langle 0.41.0 \rangle \rangle and \langle \langle 0.42.0 \rangle \rangle.
    [<0.34.0> - main_mon:84] - Starting main monitor loop.
13 1> _
```

As indicated by the above logs, the plus_one server and corresponding monitor are now executing in parallel with PID <0.34.0> and <0.33.0> that are dynamically assigned at runtime once the respective processes are spawned (lines 4 and 5). The synthesised monitor corresponding to the recursion in the formula of Section 1.3.2.1 eagerly unfolds one iteration of the formula (lines 9 and 10) exposing a conjunction construct at top level (see [20] for a detailed discussion of how recursion is handled is the resp. synthesised monitors). The "conjunction monitor" mon_and spawns its two submonitor actors once it starts executing (line 11); these correspond to the violation submonitor created from subformula [Srv ? {request, Clt, Num}] [Clt! {result, Num}] ff and the recursive submonitor created from [Srv? {request, Clt, Num}] [Clt! {result, Other}] 'X'. As before, the server is tested using the same request sent from the Erlang shell (line 14):

```
14 1> plus_one ! {req, self(), 19}.
15
    [<0.35.0> - plus_one:41] - Received request with value '19'.
16
    [<0.41.0> - formula:120] - mon_nec evaluating action:
17
18 {recv,<0.35.0>,{req,<0.38.0>,19}}.
    [<0.42.0> - formula:120] - mon_nec evaluating action:
19
   {recv,<0.35.0>,{req,<0.38.0>,19}}.
20
21
    [<0.35.0> - plus_one:46] - Sending response with value '{resp,19}', Current cnt '1'.
22
   {req,<0.38.0>,19}
23
    [<0.41.0> - formula:120] - mon_nec evaluating action: {send,<0.38.0>,{resp,19}}.
    [<0.42.0> - formula:120] - mon_nec evaluating action: {send,<0.38.0>,{resp,19}}.
    [<0.41.0> - formula:67] - mon_ff matched 'ff' action.
    [<0.42.0> - formula:180] - mon_var retrieving var 'X' from formula env and recursing.
2.7
28
    [<0.34.0> - main_mon:113] -
29
```

```
30 Main monitor/tracer received 'ff' - *** Violation detected! ***
31
32 2> _
```

The violation (PID <0.41.0>) and recursive (PID <0.42.0>) submonitor processes acquire trace events from their parent "conjunction monitor" process mon_and as soon as new trace events are reported by the EVM. For instance, the trace event generated by to the message {req, self(), 1} sent from the shell, is forwarded by mon_and to its child submonitors (lines 17-20). Next, the plus_one server computes the result and sends it back to the Erlang shell (line 21). This causes the second trace event to be generated by the system and reported by the EVM's tracing mechanism; once again this trace event is forwarded to, and processed by, both submonitors (lines 24-25). At this point, the recursive submonitor tries to unfold in preparation for the next computation (line 27), while the violation submonitor flags a violation verdict ff (line 26), which is in turn alerted to the main monitor. As a *single* detection suffices to ensure a global verdict, the main monitor terminates accordingly with ff (line 30); consult [4] for reasons why this is the case.

1.3.2.4 Running the Correct Server

So far, the plus_one successor server has been intentionally launched in bad mode in order to demonstrate how violations are handled by our monitor. We now re-instrument the system in order to emulate the correct successor server behaviour depicted in Figure 1.6b; invoking the instrument target differs only in the MFA tuple used to start the server, where instead of bad, the flag good is used:

```
duncan@term:/detecter-lite$ make instrument hml="../example/prop.hml"\
app-bin-dir="../example/ebin"\
MFA="{plus_one,start,[good]}"
```

The server should now behave correctly, and return the successor value of any numeric payload that we choose to send to it from the Erlang shell.

```
duncan@term:/example$ erl -pa ebin -eval "launcher:start()"
 1
3
   Erlang/OTP 18 [erts-7.2] [source] [smp:4:4] [async-threads:10] [kernel-poll:false]
 5
    [<0.34.0> - main_mon:38] - Started main monitor for processes/PIDs [].
    [<0.33.0> - plus_one:22] - Started PLUS ONE server with initial cnt value '0' and mode 'good'.
6
    [<0.33.0> - main_mon:24] - System to be monitored started.
   Eshell V7.2 (abort with ^G)
 8
    [<0.34.0> - main_mon:62] - Resolved procs [].
10
    [<0.40.0> - formula:152] - mon_max adding var 'X' to formula environment.
    [<0.40.0> - formula:91] - mon_and spawned processes (<0.41.0>) and (<0.42.0>).
11
12
    [<0.34.0> - main_mon:84] - Starting main monitor loop.
13
   1>
   1> plus_one ! {req, self(), 19}.
    [<0.35.0> - plus_one:41] - Received request with value '19'.
15
16
    [<\!0.41.0\!> - formula:120] - mon_nec evaluating action:
17
18
   \{recv, <0.35.0>, \{req, <0.38.0>, 19\}\}.
19
    [<0.42.0> - formula:120] - mon_nec evaluating action:
20
   {recv,<0.35.0>,{req,<0.38.0>,19}}.
    [<0.35.0> - plus_one:46] - Sending response with value '{resp,20}', Current cnt '1'.
   \{req, <0.38.0>, 19\}
    [<0.41.0> - formula:120] - mon_nec evaluating action: \{send,<0.38.0>,\{resp,20\}\}.
24
    [<0.42.0> - formula:120] - mon_nec evaluating action: {send,<0.38.0>,{resp,20}}.
    [<0.41.0> - formula:59] - mon_id no match.
    [<0.42.0> - formula:180] - mon_var retrieving var 'X' from formula env and recursing.
```

```
27 [<0.42.0> - formula:91] - mon_and spawned processes '<0.44.0>' and '<0.45.0>'.
28 2> _
```

When the client request {req, self(), 19} is submitted to the server from the Erlang shell (line 14), this again generates a response from the server answering back with the tuple {resp, 20}. Although the sequence of trace events is similar to the ones in Section 1.3.2.3, the data on these events is *different*: the server response now carries value 20 as opposed to 19. This causes the violation submonitor to terminate with an inconclusive verdict (line 25) and the recursive submonitor to unfold recursively in preparation for the next trace events (line 26). Stated otherwise, no violation is detected by the monitor up to the current point of execution.

1.4 Conclusion

We gave an overview of the tool detectEr from the perspective of a user wishing to employ this tool to verify Erlang systems at runtime. The tool automatically synthesises monitoring code from specifications written in the monitorable subset of the Hennessy-Milner Logic with maximal and minimal fixpoints identified in [23, 18]. This synthesised monitoring code is then instrumented to execute alongside the system under scrutiny, and is tasked with inferring specification satisfactions or violations by analysing the runtime execution exhibited by the system. One salient aspect of the tool is that the instrumentation employs the tracing facility of the host language virtual machine: it therefore requires no access to system source code and relies only on the application's binary files. The executions of the monitor and the system being analysed are decoupled, which may result in late (satisfactions or violations) detections from the monitor. On the other hand, the lightweight instrumentation approach adopted leaves the target system binaries untouched, which makes it possible to employ our tool in cases where (commercial) software with licenses and/or support agreements explicitly forbid the modification of binary code.

1.4.1 Related and Future Work

Apart from being a manifestation of the findings in [18], the tool detectEr was used as a starting point for a number of other investigations. In [11] the authors explored choreography reconfigurations for sub-monitors so as to lower the monitoring computational overhead, whereas in [8] the authors explored modifications to the tool to be able to synchronise more closely the executions of the system and the monitor and avoid problems associated with late detections. In other work, the investigators in [10] consider extensions to the tool that enables the runtime analysis to administer adaptation actions on the system once a violation is detected whereas in [9] the authors develop a type-based approach to ensure that runtime adaptations are administered correctly by the tool. We are presently considering tool extensions that enable monitoring analysis to be distributed across sites and also alternate monitor syntheses that guarantee a degree of property enforcement.
